LONG-TERM RESULTS OF TOTAL CONDYLAR KNEE ARTHROPLASTY IN RHEUMATOID ARTHRITIS

OLE KRISTENSEN, ADEL NAFEI, PER KJAERSGAARD-ANDERSEN, IVAN HVID, JØRN JENSEN

From the University Hospitals, Århus

We have reviewed at an average period of ten years the results of 71 consecutive primary arthroplasties with the Insall–Burstein total condylar knee prosthesis in patients with rheumatoid arthritis. Their mean age at surgery was 52 years (24 to 72).

At follow-up the overall results (Hospital for Special Surgery knee rating score) were excellent or good in 77%, fair in 11% and poor in 11%. There was residual pain in only 5% of patients with prostheses in situ; 58% could walk more than 500 m, and the median range of motion was 108°. Eight knees had been revised. Five underwent arthrodesis because of deep infection and three needed revision arthroplasty for mechanical loosening. The crude survival rate of the arthroplasties was 89%. The presence of radiolucency around the tibial component correlated significantly with the severity of residual pain.

In most cases, the indication for knee replacement is chronic joint pain not responding to conservative treatment. However, in patients with rheumatoid arthritis other factors must be taken in consideration, and these are also important when evaluating the outcome at follow-up. There are many reports of the long-term outcome of total knee replacement, but few of them deal separately with cases of rheumatoid arthritis.

We have evaluated the long-term results in patients with rheumatoid arthritis, primarily treated with the Insall-Burstein total condylar prosthesis.

PATIENTS AND METHODS

Between 1979 and 1982, we performed 139 consecutive primary total condylar knee arthroplasties on 95 patients with rheumatoid arthritis. The operative technique and the prosthesis used were those described by Insall, Tria and Scott (1979). The mean observation period was ten years (9 to 11). Thirty-five patients (49 knees) died during the observation period, 14 (19 knees) were lost to follow-up, and the remaining 46 (71 knees) were reviewed.

There were nine men (14 knees) and 37 women (57 knees) and their mean age was 52 years (24 to 72).

All patients were examined clinically and radiologically before operation. Rehabilitation began on admission, when they were instructed in active and passive muscle exercises, and in walking with crutches. Antibiotic and thrombosis prophylaxis was given to all patients. We used oral methicillin from the time of operation until the third postoperative day, and heparin 5000 IU subcutaneously twice daily from the day before operation until the patient was well mobilised, supervised active exercises and compressive stockings. The operating theatre was equipped with laminar air-flow. We aimed to achieve a tibiofemoral alignment between 3° and 10° of valgus, a neutral position of the prosthetic components (a tilt of less than 5°), a range of motion (ROM) greater than 95° and a stable knee (a maximum of 5° instability on full extension).

Lateral and anteroposterior radiographs were taken on the fifth postoperative day. Outpatient clinical and radiological examinations including a skyline view of the patella were performed 12 weeks postoperatively and at yearly intervals thereafter. Ahlbäck's (1968) classification was used pre-operatively to grade the severity of the joint destruction. The Hospital for Special Surgery (HSS) knee rating score (Insall et al 1976) was used, and the cement–bone interfaces beneath the tibial component were evaluated according to the radiolucency score approved by the Knee Society (Ewald, Hsu and Walker 1989). The tibiofemoral alignment and the tilt of the tibial component were measured in all knees.

The patients’ body-weight (W) and height (H) were measured at the time of surgery and a body-mass index...
(BMI) was recorded as W/H². Obesity was defined as a BMI > 28 (Quaade et al 1986).

Spearman's test was used for the correlation analysis and a p value of less than 0.05 was considered to be significant.

RESULTS

The HSS scores pre-operatively and at follow-up are shown in Table I. The poor group of eight consisted of five knees which had undergone arthrodesis because of deep infection, two in which revision arthroplasty had been performed for mechanical loosening and one with a recent femoral condylar fracture due to trauma. One knee in the fair group had clinical and radiological signs of loosening, and revision was planned. If the eight knees in which revision had been performed or was planned were considered as failures, the crude survival rate was 89%.

The median total score for the knees with prostheses in situ was 84 points (22 to 98). Pre-operatively, it was 48 points (24 to 76). No significant correlation was found between the total score and the radiolucency score, the tibial tilt, the tibiofemoral alignment at follow-up, or the body-mass index at the time of surgery.

The numbers and percentages of knees in the different pain intensity categories pre-operatively and at follow-up are shown in Table II. At follow-up 94% of the patients with prostheses in situ had less knee pain than pre-operatively. A highly significant correlation was found between the severity of the residual pain and the radiolucency score (r = 0.33, p < 0.01).

At follow-up 58% of the patients could walk more than 500 m compared with 8% pre-operatively, 15% could walk 100 to 500 m (33% pre-operatively) and 28% could walk less than 100 m (60% pre-operatively).

Table III shows the range of motion (ROM) pre-operatively and at latest follow-up. This was over 95° and functionally acceptable in 55% of knees at follow-up, but was between 60° and 94° in 44%. One knee had a ROM less than 60°. The median range at follow-up was 104° to 111° and the average gain was 16°.

At follow-up 85% of the knees with prostheses in situ were stable; 14% had instability of 6° to 15° and the knee with the recent femoral condylar fracture had instability of more than 15°.

The BMI showed no significant correlation with the intensity of the residual pain or with the radiolucency score.

Radiological analysis. Pre-operatively, according to Ahlbäck's (1968) scale, 16 knees were grade III, 29 were grade IV, and 19 were grade V and the median tibiofemoral alignment was 6° of valgus (20° of valgus to 8° of varus). Postoperatively, the median tibiofemoral alignment was 5° of valgus (quartiles : 3° and 6°). The median tilt of the tibial component was 3° medially in the frontal view (quartiles : 1° and 4°) and 1° anteriorly on the side view (quartiles : 1° posteriorly and 3° anteriorly).

Significant radiolucent zones (over 4 points) were seen around three tibial components (5% of the prostheses in situ). One of these knees was symptomatic with moderate pain.

No significant correlation was found between the radiolucency score and tibiofemoral alignment or the tilt of the tibial component. Nor did the combination of tibiofemoral malalignment and malpositioning of the tibial component influence the occurrence of significant radiolucent zones (Fisher’s exact test: p = 0.74).

Complications. There were eight serious complications (11%), but no deaths. One patient had patellar osteonecrosis, probably from the use of both medial and lateral
parapatellar incisions. Patelllectomy was performed and this knee was rated fair at follow-up. One comminuted femoral condylar fracture occurred after trauma necessitating revision arthroplasty, and one supracondylar femoral fracture occurred in a patient in whom there was a deep notch (7 mm) in the anterior femoral cortex. The fracture was treated by osteosynthesis, and the knee was rated good at follow-up. There were five cases of deep infection; detailed in Table IV. Regression analysis showed a linear correlation between the occurrence of deep infection and the time elapsed after surgery (slope = 0.047, correlation coefficient = 0.987, p = 0.0018).

prosthesis. This finding is in agreement with that reported by Scuderi et al (1989).

Our series of patients can be directly compared with the simultaneous series of knee replacements performed in our department for osteoarthritis (Nafei et al 1992). Using revision or recommended revision as the definition of failure, the osteoarthritic group had a significantly better ten-year crude survival of the prosthesis than the rheumatoid group (two failures out of 93 versus nine failures out of 71; Fisher's exact test: p = 0.009).

The overall results were similar as to the median total score and there was no significant difference in score

Aseptic loosening. Three patients had aseptic loosening. One 26-year-old woman who had had revision arthroplasty eight years after the primary procedure had a total score of 85 points two years after the revision. A 67-year-old woman had revision arthroplasty at nine years and one year later the knee was rated good. A 50-year-old man with bilateral replacements had progressive symptomatic loosening on one side at six years but revision arthroplasty was postponed because of the patient's cardiopulmonary status.

DISCUSSION

The indications for knee replacement in patients with rheumatoid arthritis differ substantially from those in other diagnostic groups. The disease is often progressive with involvement of many joints and also the upper extremities which limits the use of walking aids. Evaluation of the results of treatment should therefore be focused on the whole patient rather than on the surgical outcome in the knee alone. Unfortunately, the HSS knee rating score, used from the beginning of this study more than ten years ago, does not appropriately reflect this approach.

In a survivorship analysis of many different types of knee prostheses, Rand and Ilstrup (1991) found that patients with rheumatoid arthritis had a lower risk of failure than other diagnostic groups. This was not the case, however, in patients treated with the total condylar

Aseptic loosening. Three patients had aseptic loosening. One 26-year-old woman who had had revision arthroplasty eight years after the primary procedure had a total score of 85 points two years after the revision. A 67-year-old woman had revision arthroplasty at nine years and one year later the knee was rated good. A 50-year-old man with bilateral replacements had progressive symptomatic loosening on one side at six years but revision arthroplasty was postponed because of the patient's cardiopulmonary status.

DISCUSSION

The indications for knee replacement in patients with rheumatoid arthritis differ substantially from those in other diagnostic groups. The disease is often progressive with involvement of many joints and also the upper extremities which limits the use of walking aids. Evaluation of the results of treatment should therefore be focused on the whole patient rather than on the surgical outcome in the knee alone. Unfortunately, the HSS knee rating score, used from the beginning of this study more than ten years ago, does not appropriately reflect this approach.

In a survivorship analysis of many different types of knee prostheses, Rand and Ilstrup (1991) found that patients with rheumatoid arthritis had a lower risk of failure than other diagnostic groups. This was not the case, however, in patients treated with the total condylar
higher than in the osteoarthritic patients, although we
could not show statistical significance (Nafei et al 1992).
The deep infections in the rheumatoid group were almost
uniformly distributed over the observation period.

**Conclusion.** Nine to 11 years after knee arthroplasty
implant there was a high rate of pain relief and improved walking ability with a prosthesis
crude survival rate of 89%.
