We present 12 patients with synovial osteochondromatosis of the elbow treated by synovectomy. Histological review showed that seven cases were primary and five secondary osteochondromatosis. The patients with primary disease had a mean improvement in the flexion arc from a preoperative value of 40° to 123° to 5° to 128° when reviewed at a mean of nine years after operation. The secondary group had a mean improvement in the flexion arc from a preoperative value of 21° to 98° to 4° to 131° at a mean of 6.8 years after operation. There was recurrence in two of seven patients in the primary group and three of five in the secondary group. Osteoarthritis developed in six elbows in the primary and in three in the secondary group. Osteoarthritis secondary to synovial osteochondromatosis is progressive. In the established condition, the distinction between primary and secondary disease may be of greater histological than clinical relevance.

J Bone Joint Surg [Br] 2002;84-B:961-6. Received 23 August 2001; Accepted after revision 26 March 2002

Patients and Methods

The diagnosis of synovial osteochondromatosis was made in 96 patients between January 1984 and January 1999. Within this same period, loose bodies were removed from 262 elbows. Twelve patients with synovial osteochondromatosis of the elbow were identified and they were reviewed clinically and radiologically.

There were ten males and two females with a mean age at the time of treatment of 39 years (14 to 58). In six patients, the dominant side was affected. The presenting symptom was pain in 11 and there was limitation of movement in seven, of whom six had symptoms of locking or catching and one had a painless contracture. The mean interval between the initial symptoms and the first surgical intervention was six years (3 months to 20 years). One patient had an ulnar neuropathy and two had irritable ulnar nerves.

The assessment of the preoperative levels of activity was based on activities which stress the elbow as follows: manual employment and a high-demand recreational life-
style (high, 7); either manual employment or a high-demand recreational lifestyle (medium, 4); and sedentary employment and a low demand recreational lifestyle (low, 1).

In nine patients the preoperative radiographs showed loose bodies in a single compartment in seven and in several compartments in two; four patients were in the primary group and five in the secondary group. Although loose bodies may appear on radiographs to be free, this is often not the case. Synovial attachment commonly confines the loose body to one compartment. Some degree of degenerative joint disease was evident in eight patients. We classified these as severe (loss of joint space with osteophytes) in one, moderate (minimal loss of joint space with anterior and posterior osteophytes) in three, and mild (normal joint space with minimal osteophytes) in four. Surgery consisted of arthroscopic removal of loose bodies in four patients and open removal in eight; subtotal synovectomy was performed in five. Additional procedures included anterior capsulotomy in four, cheilectomy of the olecranon and coronoid in two, humeral-ulnar arthroplasty in two and transposition of the ulnar nerve in three, in two of whom it was submuscular and in one subcutaneous.

Samples from each patient were sent for histological analysis at the time of surgery and were assessed by a senior orthopaedic pathologist (Fig. 1). The criteria for diagnosing primary disease were: 1) the presence of cartilaginous tissue in the synovial membrane; 2) the presence of nodules of chondrocyte nests, with little cartilage matrix separating cells, interspersed in a fibrous matrix; and 3) cellular atypia (hyperchromasia, dumbbell-shaped nuclei and occasional binucleate cells).

All patients were sequentially assessed using the Mayo elbow performance score (MEPS)\textsuperscript{18} and subjective clinical data after a mean of 8.2 years (2 to 15).

Results

Tables I and II give the clinical details, treatment, and final outcome of this heterogeneous group. The clinical analysis was based on the histological finding of primary or secondary disease.

Symptoms in the distribution of the ulnar nerve were common with an irritable ulnar nerve in the primary group and neuropathy in the secondary group. Relief from pain was one of the principal goals for surgery. Those patients with primary osteochondromatosis had a mean improvement in the pain score from 17 (15 to 30) to 41 (30 to 45). In five patients with secondary osteochondromatosis there was a mean improvement in the pain score from 21 (0 to 45) to 42 (30 to 45).

The movement in the primary group improved from a mean preoperative range of flexion of 40° to 123° and pronation/supination of 83° to 78° to a mean postoperative range of flexion of 11° to 119° and pronation/supination of 90° to 73°. However, one patient in the primary group (case 4) represented a very atypical situation in which there were many confounding factors which adversely affected the function of the elbow including four previous treatments with radiation. When this patient was excluded from the analysis, the mean postoperative range of flexion improved to 5° to 128° and pronation/supination to 90° to 77°. The movement in the secondary group improved from a mean preoperative range of flexion of 21° to 98° and pronation/supination of 82° to 90°, to a mean postoperative flexion of 4° to 131° and pronation/supination of 82° to 80° at final review, representing a change from 16 points to 25 points on the functional score. The overall MEPS was similar in the two groups with an increase from 57 points to 94 points for the primary group and from 64 points to 97 points for the secondary group.

Five patients had recurrence of symptoms; in three further surgical treatment was required and two declined further intervention. The symptoms of recurrence were similar to those which occurred before the previous surgery and the diagnosis was confirmed on radiography. Of the two who declined further intervention, in one (secondary group, case 5) the histological diagnosis was secondary synovial chondromatosis. He had a recurrence at five years with slightly less pain in the elbow with the re-formation of loose bodies. He received conservative treatment and was

able to resume manual employment. The second patient (primary group, case 4) was from overseas and had had multiple operations before his treatment at our institution, including open debridement, radiation therapy and intensive physiotherapy. Severe intra- and extra-articular adhesion and scarring were noted at operation and the chondral surfaces had undergone widespread stage-II and stage-III degenerative changes. After removal of the loose bodies and total synovectomy, a circumferential capsulotomy was performed. Stiffness and pain recurred, but his symptoms were an improvement on the preoperative state and he was unwilling to consider further intervention.

Of the three patients who were operated on for recurrent symptoms, the histological diagnosis was secondary disease in two (secondary group, cases 1 and 3) and primary disease in one (primary group, case 2). The former two underwent total elbow arthroplasty (case 1) and debridement, humeroulnar arthroplasty and resection of the radial head (case 3). The third patient had two recurrences after initial surgery at another hospital, and two further recurrences after surgery at our institution. The elbow was debrided again when the symptoms became unmanageable by conservative measures and an anterior capsulotomy was performed. At the initial presentation no loose bodies had been visible on plain radiography, but a single loose body was removed from the lateral gutter, and a pedunculated partially calcified body was evident at recurrence (Fig. 2).

Before surgery, osteoarthritic changes were severe in one patient, moderate in three, and mild in five. At final review there was one case of severe, three of moderate, and four of mild OA. One of the patients with moderate OA had a total elbow arthroplasty because of rapid symptomatic progression and intraoperative findings of significant chondral destruction (secondary group, case 1). The patients with OA in the primary group showed no deterioration from the time of surgery to the final follow-up, whereas in the secondary group, one progressed from mild to moderate OA in spite of a further debridement (secondary group, case 3).

Discussion

A review of the literature on primary synovial osteochondromatosis highlights two issues first, that the definition and criteria by which the diagnosis is made, are unclear, and secondly, that little is known about this disorder. Clinically, the symptoms and signs are not specific and may suggest several differential diagnoses. The clinical presentation is commonly of pain, mechanical symptoms, and/ or loss of movement, none of which is specific. Pain may follow exertion but may also be due to effusion, locking, nerve compression or secondary osteoarthritic changes. The inability fully to extend the elbow was thought to be the first significant symptom followed by catching and locking. Stiffness of the elbow is not a characteristic feature of the primary condition. All 12 patients in our study had a reduced range of extension >10° with a mean of 40° (15 to 55) in the primary group (with the exclusion of case 4 for reasons of multiple confounding features), and 21° (10 to 40) in the secondary group. Whereas the primary group mostly had an extension deficit, the secondary group had less extension deficit and greater flexion deficit. In both groups, however, the deficits were amenable to surgical release. Symptoms in the ulnar nerve have been reported twice. Our findings serve to highlight that spontaneous symptoms in the ulnar nerve can be caused by either primary or secondary synovial osteochondromatosis due to pressure from swelling or as part of a contracture.
Plain radiographs are said to reveal that between 66% and 80% of all loose bodies are caused by synovial chondromatosis. In our series five of the seven primary patients had radiologically visible lesions. Some degree of calcification of cartilage is present in 60% and ossification in 55% of cases. Not all radiographs show the typical appearances of primary synovial chondromatosis (Figs 3 and 4) and some serve to confuse between the primary and secondary conditions (Fig. 5). Ultrasonography has demonstrated lesions which were not detected on plain radiographs, as has arthrography, CT and arthro-CT scanning.

Both operative and non-operative treatments have been described for the management of synovial osteochondromatosis. Relief from pain has been reported with conservative management. A non-surgical approach has also been advocated for the disease in phases II and III, with the latter authors recommending any necessary treatment when the disease has become quiescent, suggesting an improved outcome. However, most authorities recommend surgery, although the extent of the intervention varies. Recurrence after removal of an isolated loose body has led some authors to advise adjunctive synovectomy for all cases. Whereas most published studies recommend synovectomy in some form, its value has been questioned in the light of reports showing no differences in outcome after debridement and synovectomy. Our experience also suggests that extensive synovectomy is not always necessary for inactive disease since four patients in the primary group were treated successfully by debridement alone. This allows a more selective use of adjunctive synovectomy, particularly when the histological findings indicate an active pathological process.

The reported incidence of recurrence is between 0% and 22%. The cause is usually assumed to be incomplete removal of loose bodies and/or diseased synovium. The true incidence of recurrence, however, is as uncertain as the initial diagnosis with respect to the symptoms of recurrence compared with the symptoms at initial presentation. If the cause is truly the incomplete removal of pathological tissue, it is difficult to explain the recurrence in case 2 (primary group) in which at this site a repeated subtotal synovectomy had been carried out and yet there were two further recurrences (Fig. 2). Recurrence has also been linked to high levels of physical...
activity, but two patients in our series with recurrent disease were not particularly active.

The association between synovial chondromatosis and OA has been reported as either non-existent or rare. Our observations suggest a common pathway for all loose bodies as an etiology for degenerative change. Of those patients with a recurrence who underwent further surgery, the stage of OA remained unchanged. Patients presenting at longer intervals had a more advanced stage of OA, but this also remained relatively unchanged at the final follow-up. Our findings suggest that repetitive synovectomy and removal of loose bodies may delay the progression of degenerative changes, which corroborates the findings of Gilbert and Lachiewicz.

From our study we deduce that the histological distinction between the primary and secondary diseases adds little to our understanding of stiffness, recurrence, and secondary OA since they behave similarly. Stiffness associated with primary and secondary synovial osteochondromatosis responds well to surgery, especially with regard to restoring extension. Primary synovial osteochondromatosis can recur after subtotal synovectomy and recurrence may be associated with surgical intervention at an earlier, more active, stage in the process of the disease. OA secondary to synovial osteochondromatosis appears to progress, but in early primary disease does not appear to progress beyond the stage at which definitive surgery is performed. No benefits in any form have been received or will be received from a commercial party related directly or indirectly to the subject of this article.
