Elective Caesarean section is associated with a reduction in developmental dysplasia of the hip in term breech infants

We wished to establish whether delivery by Caesarean section influenced the incidence of developmental dysplasia of the hip in term breech infants compared with those delivered vaginally. We used maternal charts, singleton term breech presentation, mode of delivery and incidence of developmental dysplasia of the hip for births between January 1997 and October 2002.

During the study period 46,089 infants were born. We analysed a total of 941 breech infants of whom 756 were delivered by Caesarean section (515 pre-labour, 241 intrapartum) and 185 vaginally. The incidence of developmental dysplasia of the hip according to the mode of delivery was 19 of 515 (3.69%) following pre-labour Caesarean section, 16 of 241 (6.64%) for intrapartum Caesarean section and 15 of 185 (8.11%) after vaginal delivery. There was a lower incidence of developmental dysplasia of the hip among those infants delivered by elective Caesarean section compared with those delivered vaginally (p < 0.02). These results demonstrate a significantly lower incidence of developmental dysplasia of the hip in term singleton breech births delivered by elective, pre-labour Caesarean section and suggest that labour and delivery influence hip stability in predisposed infants.

Breech presentation is an important risk factor for developmental dysplasia of the hip (DDH).1-4 It is understood that the presentation rather than mode of delivery is the critical factor in promoting dislocation.5

The obstetric management of term singleton breech deliveries has been greatly influenced by the results of the Term Breech Trial in 2000.6 This study concluded that reduced perinatal morbidity is associated with term singleton breech births undertaken by elective Caesarean section. In 2001, the Royal College of Obstetrics and Gynaecology published guidelines supporting this conclusion.7 It was our clinical impression that since this change in delivery policy there was a reduction in the number of breech infants with DDH.

This study examined whether the mode of delivery plays a role in DDH in term singleton infants presenting by the breech.

For each breech birth, the mode of delivery was categorised as vaginal, emergency caesarean section in labour or elective pre-labour Caesarean section. For each breech infant, the records were examined to identify those with DDH and correlate them with mode of delivery.

During the study period all breech infants whose hips were clinically normal had an additional hip ultrasound examination at six to eight weeks of age using the Graf technique.8,9 Any additional cases of DDH identified by ultrasonography were related to the mode of delivery.

Results
During the 70-month period 46,089 infants were born in the National Maternity Hospital, of whom 941 fulfilled our inclusion criteria. There were 756 deliveries by caesarean section and 185 vaginal births.

Of the 941 infants, 47 had clinical evidence of DDH and a further three were identified at eight weeks of age by ultrasound. There were 20 bilateral dysplasias, 16 right hip only and 14 left hip only. The breech classification comprised 39 extended, four flexed and seven unspecified. There were 38 girls and 12 boys. Among the mothers, 42 were primiparous and
eight multiparous. The mean birth weights for the infants with DDH according to delivery category were: 3.33 kg (2.43 to 4.02) vaginal, 3.43 kg (2.89 to 4.07) emergency Caesarean, 3.79 kg (2.84 to 4.77) elective Caesarean.

Table I illustrates the relationship between DDH and breech presentations and mode of delivery. The DH incidence among vaginal breech births was 15 of 185 breech births (8.11%), compared with 16 of 241 (6.64%) for emergency Caesarean sections and 19 of 515 (3.69%) for elective pre-labour Caesarean sections.

The incidence of DDH was significantly different between breech infants delivered vaginally and those delivered by elective Caesarean section (8.11% vs 3.69%; p < 0.02; chi-squared 5.75).

Discussion

Our findings indicate that the mode of delivery influences the incidence of DDH in infants in breech presentation. Those delivered vaginally had an incidence more than double that of breech infants delivered by pre-labour Caesarean. The relationship between breech presentation, mode of delivery and DDH has previously been studied with varying conclusions.\(^{10-12}\) In a study of 583 breech deliveries, Clausen and Nielsen\(^{10}\) found no difference in the frequency of DDH when comparing those delivered by Caesarean section and those delivered vaginally. They did not, however, divide their Caesarean population into emergency and elective groups as we have done, thereby demonstrating higher rates of DDH in the vaginal delivery group.

We suggest the force of labour on the fetal hip contributes to DDH. Further support of this concept was suggested by Moore\(^{13}\) who held that repeated or forceful neonatal hip examination may lead to hip dislocation. He maintained that stretching the joint capsule was the likely cause and examination may lead to hip dislocation. He maintained that stretching the joint capsule was the likely cause and examination may lead to hip dislocation.

When considering the birth weights of breech infants with DDH, we found the heavier infants were in the group with the lowest incidence of DDH (elective Caesarean section). We know from previous studies that the incidence of DDH is greater among larger babies.\(^2\) Our observations exclude the possibility that higher birth weights among the babies delivered vaginally could explain the greater incidence of DDH.

We calculate that for every 1000 term singleton breech presentations there would be 81 cases of hip dislocation if all were delivered vaginally compared with 37 if all were delivered by elective caesarean section. This represents a 54% reduction in DDH. In Ireland, with approximately 60 000 births per year, one would expect approximately 1800 breech presentations at term. If all these infants were delivered by elective Caesarean section one could expect to prevent 80 cases of DDH per year. This not only represents a major financial benefit but also indicates the magnitude of the mechanical effects of labour on the hip joint in term breech cases.

Our study indicates that the mode of delivery has a significant influence on the incidence of DDH and, furthermore, gives additional insight into the aetiology of DDH, particularly the importance of mechanical factors.
