Radiological evidence of femoroacetabular impingement in mild slipped capital femoral epiphysis

A MEAN FOLLOW-UP OF 14.4 YEARS AFTER PINNING IN SITU

C. R. Fraitzl, W. Käfer, M. Nelitz, H. Reichel

From the University of Ulm, Ulm, Germany

Conventional treatment of mild slipped capital femoral epiphysis consists of fixation in situ with wires or screws. Recent contributions to the literature suggest that even a mild slip may lead to early damage of the acetabular labrum and adjacent cartilage by abutment of a prominent femoral metaphysis. It has been suggested that the appropriate treatment in mild slipped capital femoral epiphysis should not only prevent further slipping of the epiphysis, but also address potential femoroacetabular impingement by restoring the anatomy of the proximal femur.

Between October 1984 and December 1995 we treated 16 patients for unilateral mild slipped capital femoral epiphysis by fixation in situ with Kirschner wires. In this study we have reviewed these patients for clinical and radiological evidence of femoroacetabular impingement. There was little clinical indication of impingement but radiological evaluation assessing the femoral head-neck ratio and measuring the Nötzli α angle on the anteroposterior and cross-table radiographs showed significant alterations in the proximal femur. None of the affected hips had a normal head-neck ratio and the mean α angle was 86˚ (55˚ to 99˚) and 55˚ (40˚ to 94˚) on the anteroposterior and lateral cross-table radiographs, respectively.

While our clinical data favours conventional treatment, our radiological findings are in support of restoring the anatomy of the proximal femur to avoid or delay the development of femoroacetabular impingement following mild slipped capital femoral epiphysis.

Clinically symptomatic or silent slipping of the capital femoral epiphysis is one mechanism that leads to the development of cam-type femoroacetabular impingement and subsequent osteoarthritis (OA) of the hip. The treatment of slipped capital femoral epiphysis (SCFE) is usually surgical and depends on the severity of the slip, generally defined by the angulation of the femoral epiphysis relative to the axis of the femoral neck. For mild slips, with angulation < 30˚, fixation of the epiphysis in situ by smooth pins or screws is recommended in the literature as well as in the German national guidelines. Two reports, with a mean follow-up of 31 and 41 years respectively, showed good long-term results for pinning in situ, not only in mild but also in moderate and severe slips.

However, two recent publications have suggested that soon after slipping of the epiphysis, changes occur at the acetabular labrum and adjacent cartilage which are precursors of OA of the affected hip joint. In these two studies, after arthroscopy and surgical dislocation as described by Ganz et al, intra-articular evaluation of the hip joints revealed erosions, scars and/or tears of the labrum, with damage to the articular cartilage ranging from superficial abrasions to full-thickness loss caused by a prominent femoral metaphysis protruding beyond, or at least level with, the epiphysis.

These findings led the authors to recommend that in mild SCFE, in addition to stabilization of the epiphysis in situ an osteochondroplasty at the femoral head-neck junction should be performed in an attempt to reduce the risk of developing secondary osteoarthritis. If this advice was followed in mild SCFE a small procedure would be replaced by an invasive operation, with the potential risk of producing avascular necrosis of the femoral head. However, surgical dislocation of hips with SCFE has been reported as part of treatment in a limited number of patients. No severe adverse effects were reported, or in the patients described by Leunig et al. In an attempt to substantiate this newly-proposed therapeutic approach to the deformity resulting from mild SCFE, and as femoroacetabular impingement typically becomes sympto-
a unilateral mild SCFE by pinning with Kirschner (K)-wires in situ. These 35 years. We reviewed those patients who were treated in our department between October 1984 and December 1995 for a unilateral mild SCFE by pinning with Kirschner (K)-wires in situ. They were evaluated both clinically and radiologically, with the unaffected but prophylactically-pinned contralateral hip serving as an internal control.

**Patients and Methods**

This study was approved by our institutional Human Experiment and Ethics Committee and informed consent was obtained from all the patients examined.

Between October 1984 and December 1995, 73 patients were admitted for the treatment of SCFE and three for other conditions. Of the 76 patients, 51 were male and 25 were female. For six patients documentation was incomplete, 15 had undergone an intertrochanteric osteotomy, in 13 screw fixation of the slipped epiphysis was performed, and in one patient only the affected hip was pinned in situ. These 35 patients were excluded. Of the remaining 41 patients, eight had a bilateral slip and in four, a closed reduction was performed, leaving 29 patients with unilateral SCFE and a slip angle < 30°, except for one patient with a slip angle of 31°, who was still included in the study. All 29 patients had undergone pinning of the affected and unaffected epiphysis using K-wires. A total of 16 patients could be contacted and evaluated.

Before evaluation, the documented angles of slip were remeasured on the lateral Lauenstein radiographs taken at first presentation. The extent of the slip was determined by measuring the angle between the base of the slipped epiphysis and a line perpendicular to the axis of the femoral neck.

The occupation and sports activities of the patients according to the activity score of Tegner and Lysholm were recorded (Table I). Clinical examination included recording the range of movement of both hips and the impingement provocation test, where pain in the groin is potentially provoked by internal rotation and adduction in 90° flexion, when lesions of the acetabular labrum are present.

Radiological evaluation was performed using anteroposterior (AP) radiographs of the pelvis and lateral cross-table views of both hips. The head-neck ratio of the proximal femur was described qualitatively for both planes by assigning it to one of four groups: normal ratio, mildly reduced ratio, reduced ratio or markedly reduced/completely lacking. A mildly reduced ratio was assumed when a reduction of the head-neck ratio by approximately half of the normal ratio was present. A markedly reduced ratio was defined according to Nötzli et al by a line connecting the centre of the femoral head with the centre of the femoral neck and a line connecting the centre of the femoral head with a point on the head-neck contour where the latter leaves a circle projected over the femoral head. The α angle is 99°.

Anteroposterior pelvic radiograph of a 28-year-old man, approximately 12 years after in situ pinning of both proximal femora. The unaffected right hip shows a normal head-neck junction; the affected left hip has a markedly reduced head-neck ratio and a bony prominence at the head-neck junction. Angle α is defined according to Nötzli et al by a line connecting the centre of the femoral head with the centre of the femoral neck and a line connecting the centre of the femoral head with a point on the head-neck contour where the latter leaves a circle projected over the femoral head. The α angle is 99°.
cance was examined using the Wilcoxon's matched-pairs signed-ranks test, Fisher's exact test or the chi-squared test for independence, according to the characteristics of the investigated data. The level of significance was set at \( p < 0.05 \).

**Results**

All 16 patients were Caucasian. There were 13 males and three females. In 12 males and two females, the left hip was affected and in one male and one female, the right hip was affected. The mean age of the patients on admission was 13.6 years (11.8 to 17.1) and the mean period of follow-up was for 14.4 years (11.3 to 21.2). The mean angle of slip was 17˚ (12˚ to 31˚). The femoral epiphysis had been pinned on the affected side with three K-wires in four hips, with four in eight, five in three, and six in one, and on the unaffected side with three K-wires in five hips, four in ten and five in one. There was no statistically significant difference in the number of wires applied between the affected and unaffected sides (Wilcoxon's matched-pairs signed-ranks test, \( p = 0.063 \)). All the pins had been placed through a lateral skin incision distal to the greater trochanter and after the fascia lata had been split over a small distance.

When grading activity according to Tegner and Lysholm,\textsuperscript{24} one patient had an activity level of 3, eight a level of 4, five a level of 6 and two a level of 9. These latter two both played competitive football but had sedentary occupations. Clinical examination revealed mean flexion of 112˚ (90˚ to 130˚) in the affected and 113˚ (90˚ to 135˚) in the unaffected hip, internal rotation was a mean of 16˚ (5˚ to 30˚) in the affected and 23˚ (10˚ to 35˚) in the unaffected hip, and the mean abduction was 38˚ (25˚ to 55˚) in the affected and 42˚ (30˚ to 55˚) in the unaffected hip. Statistically significant differences were found for internal rotation (Wilcoxon's matched-pairs signed-ranks test, \( p < 0.01 \)) and abduction (Wilcoxon's matched-pairs signed-rank test, \( p = 0.02 \)), but not for flexion (paired \( t \)-test, \( p = 0.43 \)) between the affected and the unaffected hips. The impingement provocation test was found to be positive in six affected and five unaffected hips, which was not statistically significant (Fisher's exact test, \( p = 1.0 \)) (Table II).

Radiological evaluation of the head-neck ratio revealed an absent or distinctly reduced ratio in ten affected hips and four unaffected hips, a reduced ratio in two affected hips and one unaffected hip, a mildly reduced ratio in four from each group and a normal ratio in none of the affected hips.
and seven of the unaffected hips. A statistically significant difference was found between the affected and the unaffected hips (chi-squared test for independence, \( p < 0.02 \)). Significantly more bony prominences at the head-neck junction were found in the affected hips than in the unaffected hips (Fisher's exact test, \( p < 0.03 \)) (Table III).

Measurement of the \( \alpha \) angle revealed a statistically significant difference between the affected and unaffected hips. It was a mean of 86° (55° to 99°) and 62° (45° to 90°) (Wilcoxon’s matched-pairs signed-ranks test, \( p < 0.01 \)), respectively, on AP radiographs and 55° (40° to 94°) and 46° (33° to 68°) (Wilcoxon’s matched-pairs signed-ranks test, \( p = 0.03 \)), respectively on cross-table radiographs (Table IV). In both planes the majority of the deformity of the head-neck contour occurred laterally.

**Discussion**

Only recently has femoroacetabular impingement been described as one possible mechanism for developing OA of the hip joint.\(^4,6,7,9,15,17-19,28-30\) Structural abnormalities of the acetabular rim and/or the anterolateral head-neck junction of the proximal femur may lead to either pincer-type impingement, a cam-type impingement, or a combination of both. For cam-type femoroacetabular impingement the underlying conditions are not yet clarified. Besides a growth abnormality of the capital femoral epiphysis,\(^1,9\) subclinical and clinical SCFE are discussed as one possible cause for a reduced or absent head-neck ratio.\(^1,9\) Many studies consider different diagnostic or therapeutic options in SCFE in the short and long term.\(^10,12,13,32,33\) but do not describe the mid-term, when femoroacetabular impingement typically evolves. Follow-up of between seven and 16 years is documented in a few studies from the 1950s to the 1980s, prior to the recognition of femoroacetabular impingement.\(^11,34-36\)

We have studied patients who suffered from SCFE in their adolescence and are now at the age when symptoms of impingement are typically manifest.

Although originally developed for the evaluation of patients with knee ligament injuries, the Tegner and Lysholm activity score\(^24\) revealed that more than half of our patients, with a mean age of 28.1 years at follow-up, did not exceed level 4, suggesting that the functional outcome precluded more athletic pursuits.

When looking at the range of movement, flexion, internal rotation and abduction are predominantly restricted by the metaphysis becoming prominent through posterior and medial displacement of the epiphysis.\(^7\) There was a significant reduction of internal rotation and abduction, but not of flexion, which would be expected to occur in femoroacetabular impingement. Additionally, the extent of the internal rotation, although restricted compared with the normal hip, was more than the maximum of 10° typically assumed for femoroacetabular impingement.\(^6\) However, it must be acknowledged that there is no linear relationship between the loss of internal rotation and the extent of the damage caused by impingement after SCFE, because in mild slips the prominence of the metaphysis may still enter the joint and abraid the acetabular cartilage, in contrast to moderate or severe slips, where a larger metaphyseal prominence may be obstructed from entering the joint by the acetabular rim.

The ventral impingement provocation test,\(^25\) although not specific, is positive in the vast majority of patients with symptomatic femoroacetabular impingement.\(^6,18\) but in our group it was positive in less than half the affected hips. Furthermore, it was positive in five unaffected hips, which may suggest a systemic growth disturbance in SCFE, leading to bilateral.\(_{13,33,37,38}\)

The radiographs demonstrated considerable changes in the head-neck ratio, with no affected hips, and only seven of the unaffected hips having a normal ratio. Bony prominences at the head-neck junction were found in 13 of the affected but only six of the unaffected hips.

The normal \( \alpha \) angle is considered to be 42°.\(^26\) The mean \( \alpha \) angle on the AP radiographs was 86° in the affected and 62° in the unaffected side. Although this constituted a significant difference between the affected and unaffected hips, both values clearly differ from the norm, showing that although prophylactically pinned, the unaffected side did not develop normally. This may be as a result of a systemic disturbance of development of the growth plate in affected individuals, as suggested by the frequent bilateral presentation,\(_{13,33,37,38}\) or a disturbance induced by the operative procedure itself.

From the cross-table radiographs, the mean \( \alpha \) angle was 55° for the affected and 46° for the unaffected side, which was a statistically significant difference, but differed less from the normal value of 42°, especially for the unaffected side. Remodelling of the head-neck junction has been proposed by Bellemans et al\(^{35,36}\) as one important process leading to good long-term results observed after in situ pinning in SCFE and obviously takes place at a favourable site, anteriorly. This may explain why the majority of our patients, although following less physically demanding life-styles perform well for 10 to 20 years after in situ pinning of the SCFE.

In conclusion, there were few clinical signs of femoroacetabular impingement 10 to 20 years after in situ pinning. However, radiological evaluation supports the proposition that proximal femoral osteochondroplasty might avoid or delay the development of femoroacetabular impingement after mild SCFE.
