Remodelling of the distal radius after epiphysiolysis and lengthening

Arrest of growth of the distal radius is rare but will produce deformity of the wrist. We corrected angular deformity and shortening of the distal radius by epiphysiolysis and gradual lengthening without a corrective osteotomy.

Little is known about remodelling of the distal radius in children, but the spontaneous correction of angular deformities of growing long bones is a well-known phenomenon in clinical practice.1-3 Because growth arrest of the distal radius is rare, treatment options are limited. Here we describe a case treated for growth arrest of the distal radial physis.

Case report
A nine-year-old girl was seen with a deformity of the right wrist. Plain radiographs (Fig. 1), and an MRI (Fig. 2) showed physeal bar formation at the distal radius and a complex deformity. She had injured her right wrist three years previously and had been treated conservatively. Joint movement was normal except for ulnar and radial deviation. The physeal bar was resected and bone cement (polymethylmethacrylate) interposed in the distal radial physis. Corticotomy was performed and an Ilizarov external fixator (U & I Co-operation, Gyeonggi-do, Korea) applied to the distal radius. Seven days later, lengthening of the radius was started at 1 mm/day and was terminated after 2 cm of gain when the distal radial physis and ulnar joint line were level (Fig. 3). Two years later the radial inclination and height had corrected spontaneously, and the deformity was cured (Fig. 4).

Discussion
Growth arrest of the distal radius is rare and is related to many factors, including the severity of trauma, the degree of displacement, and repeated or delayed reduction.4 Clinically, relative lengthening of the ulna accentuates degeneration of the triangular fibrocartilage complex,5 and radial shortening can disrupt the mechanics of the distal radioulnar joint and result in loss of movement.6

The treatment of growth arrest of the distal radius aims to re-establish normal growth and correct deformity. Residual deformities can be corrected by equalising the lengths of the...
radius and ulna by resection of the radial physeal bridge and epiphysiodesis of the distal ulna, or by ulnar shortening. However, an angular deformity of the distal radius of more than 20° will probably not correct with growth after excision of the physeal bar, and usually requires an osteotomy.

In this case, corrective osteotomy was not performed. The physeal bar was resected with interposition of bone cement and bone lengthening. Osteotomy and lengthening can increase the blood flow to adjacent tissues and stimulate the growth plate of the distal radius. The distal growth plate accounts for 75% of the length of the bone, permitting substantial remodelling.
