CASE REPORT

Hip pain many years after fusion
A REPORT OF TWO CASES

K. Wong, T. P. Ng, K. Y. Chiu
From Queen Mary Hospital, Hong Kong

Arthrodesis of the hip has been employed since the late 19th century. Late complications can arise decades after fusion in patients who were previously asymptomatic. We describe two patients who developed pain in the hip many years after a successful fusion. There was no infection or loosening of the implants. After careful investigation, including oblique radiographs and diagnostic injections of local anaesthetic, the pain was found to be caused by protrusion of the implant. Subsequent removal of the device resulted in complete resolution of the symptoms.

Arthrodesis of the hip was first described in the late 1800s and many different techniques have since been used. The objective is to obtain a stable and pain-free joint. We describe two patients, treated by arthrodesis of the hip many years ago, who presented with hip pain. Although pain after hip fusion is not uncommon, careful clinical assessment and investigation is essential, as the cause of the pain may prove elusive.

Case 1
A 55-year-old man presented with an eight month history of increasing pain in the right hip and knee. He had undergone arthrodesis of the right hip 24 years previously and had subsequently been well and pain free. He denied any trauma to the hip. The pain increased with activity and was relieved by rest. There was no history of fever, night pain or pain at rest. On examination, the hip was fused in 30˚ of flexion, 5˚ of external rotation and 5˚ of adduction. There was mild tenderness in the groin, but at no other sites. There were no enlarged lymph nodes and no evidence of a hernia. Examination of the knee joint was unremarkable. A radiograph of the pelvis showed solid fusion of the right hip with two Smith-Petersen nails. There was no fracture and no evidence of loosening of the implants. Blood tests showed no abnormality and all infective markers were within normal limits. A bone scan was performed which showed no increase in uptake in the hip. An obturator oblique plain radiograph of the right hemipelvis (Fig. 1) showed that the tip of the upper Smith-Petersen nail was protruding through the cortex of the right ilium. A CT scan of the pelvis confirmed that the tip of this nail was impinging on the right iliacus muscle. To confirm that the pain was because of this impingement, a diagnostic test was undertaken with local anaesthetic (Fig. 2). Under fluoroscopic control, a needle was inserted to the tip of the nail and 14 ml of 0.5% Marcaine injected. This was followed by resolution of the pain. Both nails were removed and he has remained pain free and mobile during the subsequent six years.
Case 2
A 69-year-old woman presented with a 19-year history of pain in the right hip. She had undergone an arthrodesis of the hip 33 years previously for tuberculosis. She had fallen in 1981, sustaining a right subtrochanteric fracture. The fracture was treated by open reduction and internal fixation. The hip had remained painful since the operation. It was present at rest and aggravated by walking and prolonged sitting. She required regular analgesia.

On examination, there was a leg-length discrepancy of 6 cm. The right hip was solidly fused in a satisfactory position. She was tender over the anterior aspect of the fused hip joint, but there was no tenderness on passive movement of the lower leg. There were no enlarged lymph nodes and no evidence of a hernia. Infective markers and a bone scan were normal. A CT scan confirmed bony ankylosis of the joint. However, an oblique radiograph with the pelvis and femur externally rotated showed the tip of a screw protruding through the neck of the femur (Fig. 3).

Injection of local anaesthetic into this site under fluoroscopic control resulted in complete resolution of the pain. The screw was removed and she has been pain free for the subsequent six years.

Discussion
The patient with an arthrodesed hip may present with ipsilateral or contralateral hip pain, ipsilateral knee pain or back pain.2,6 Late local complications include infection, fracture and implant failure.3,7-9 Most large series of hip fusions report an infection rate of around 5% in the early post-operative period.3,4,7-9 However, there are no figures for the development of late infection. Fractures of the femoral neck, especially of the base, are not uncommon. Fractures of the femoral shaft have been reported in up to 10% of patients on long-term follow-up.3,4,6-9 Implant failure, usually bending or breakage, is also not uncommon. However, there has been no previous report of implant protrusion causing impingement and pain. Plain radiographs correctly orientated can be useful to detect protrusion of an implant. When impingement is suspected, the injection of local anaesthetic can be a quick and effective way of confirming the diagnosis. We would recommend the use of a longer-acting anaesthetic such as Marcaine to better observe the effect, and the subsequent removal of the impinging implant if indicated, as in the two patients reported here.
